# outline

- 1 dynamic matching: some contexts and background
  - sponsored search and ad displays
  - kidney exchange programs
  - online optimization framework
- 2 online bipartite matching problems
- 3 matching markets for kidney exchange

	<b>sponsored search</b>	<b>display</b>
<b>marketer</b>	get clicks and conversions	build brand awareness
<b>publisher</b>	search engine	(almost) any website
<b>matching</b>	publisher	third party

kidney transplant: best treatment for end stage renal disease.

- 99,379 patients on the waiting list in the US as of yesterday<sup>1</sup> [France: 21,000 people waiting for a kidney in 2015 (up from 12,000 in 2006)]
- over 30,000 new patients each year in the US
- only 18,000 transplants per year [France: 3,500 in 2015]
- about 12,000 from deceased donors [France: 3,000 in 2015]

<sup>1</sup>United Network for Organ Sharing (UNOS) <http://www.unos.org/>

# online concepts

- **online optimization problem** = instance incrementally revealed over time; need to make decisions “online” without knowledge about what comes next.
- **online algorithm**:
  - the “quality” of an online algorithm  $ALG$  is its **competitive ratio**  $c$ , measured against an optimal clairvoyant algorithm  $OPT$  with full knowledge of the instance; for a maximization problem:

$$c = \sup \{ r \mid \text{alg}(i)/\text{opt}(i) \geq r, \forall \text{ instances } i \}$$

- it is said to be **best possible** if there is no other such algorithm with a larger competitive ratio.

## ... online concepts ...

- **randomized online algorithm**: online algorithm with random steps designed to solve an online problem.
- competitive analysis depends on the **“power of the offline adversary”**:
  - oblivious adversary: doesn't know the realizations of the random steps.
  - adaptive-online adversary: generate the instance adaptively based on past realizations of the random steps.
  - adaptive-offline adversary: perfect knowledge of all the realizations (past and future) of the random steps.
- we consider only **oblivious** adversary.

## ... online concepts ...

- **competitive ratio** of a **randomized** online algorithm against an oblivious adversary:

$$c = \sup \{r \mid \mathbb{E}[\text{ALG}(i)]/\text{opt}(i) \geq r, \forall \text{ instances } i\}$$

- a randomized online algorithm is said to be **best possible** if there is no other such algorithm with a larger competitive ratio

## ... online concepts

- in some cases **uncertainty** about the future input streams can be modeled using **probabilistic concepts**.
- how to properly include this “**stochastic information**” in order to **design better algorithms**? can this be **quantified**?
- look at the **competitive ratio** of an online algorithm defined as

$$c = \sup \{ r \mid \mathbb{E}_{\mathbb{P}}[\text{ALG}(I)/\text{OPT}(I)] \geq r \}$$

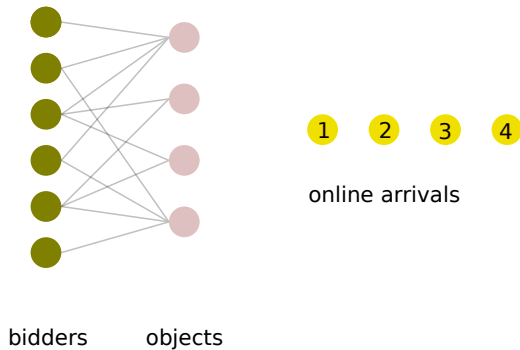

- sometimes can show results hold “with high probability” as opposed to simply “in expectation”.

## online bipartite matching: summary of main results

- for the adversarial model:
  - no deterministic online algorithms can do better than 0.5
  - the *ranking* algorithm of KVV90 provides a best possible randomized algorithm with competitive ratio  $1 - 1/e \approx 0.632$

# online bipartite matching: summary of main results

  - the *ranking* algorithm of KVV90 provides a best possible randomized algorithm with competitive ratio  $1 - 1/e \approx 0.632$

- what about the case of random inputs, i.i.d. with known distribution?
  - FMMM09 prove for the first time that one can do better under an i.i.d. stochastic model and give a 0.670-competitive algorithm under this scenario.
  - MOS13 provide a 0.702-competitive algorithm
  - in JL14, we obtain a  $(1 - 2/e^2 \approx 0.729)$ -competitive algorithm, best-known so far

## an overall approach

- given an i.i.d. model with known distribution, by solving an optimal maximum cardinality matching for each possible i.i.d. draws, one could “calculate”  $p_{ik}^*$  the probability that edge  $(i, k)$  is part of an optimal solution in any given random realization ...

## an overall approach

- given an i.i.d. model with known distribution, by solving an optimal maximum cardinality matching for each possible i.i.d. draws, one could “calculate”  $p_{ik}^*$  the probability that edge  $(i, k)$  is part of an optimal solution in any given random realization ...
- ... instead of computing  $p_{ik}^*$ , we formulate special maximum flow problems whose optimal solutions provide the input for the design of good online algorithms.

# a maximum flow problem for the case of i.i.d. uniform

under the i.i.d. uniform assumption one can show

$$p_{ik}^* \leq 1 - 1/e \approx 0.632 \quad \forall (i, k) \in E.$$

$$\begin{aligned} \max \quad & \sum_{(i,k) \in E} x_{ik} \\ \text{s.t.} \quad & \sum_{k:(i,k) \in E} x_{ik} \leq 1 \quad \forall i \in B \\ & \sum_{i:(i,k) \in E} x_{ik} \leq 1 \quad \forall k \in O \\ & x_{ik} \in [0, 2/3] \quad \forall (i,k) \in E \end{aligned}$$

⇒ competitive ratio =  $1 - 2/e^2$

## Second Part: Matching Markets for Kidney Exchange

## kidney exchange

## kidney exchange

## kidney exchange

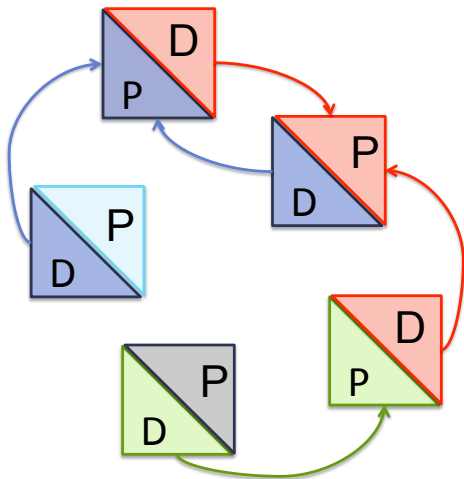

## kidney exchange

## kidney exchange

## kidney exchange

## data

- blood-type compatibility:

- tissue-type compatibility: the likelihood of being compatible with a random donor (from a compatible blood type) is measured by the PRA (panel reactive antibodies): low PRA = highly compatible.

# data and model - thickness and heterogeneity

- **thickness**: how easy is it for a typical patient to get a “match”?
- **tissue-type compatibility**:
  - high PRA = “hard” to match
  - low PRA = “easy” to match

- bimodal distribution  $\Rightarrow$  **two-type model**:
  - hard-to-match (H): typical probability  $p_H = 2.5\%$
  - easy-to-match (E): typical probability  $p_E = 90\%$

# main questions

- how to match in an heterogeneous environment?
- how do myopic (greedy in time) algorithms perform?
- how does the composition of the pool impact the types of exchanges needed to achieve the best performance?

## modeling assumptions

- an incompatible patient-donor pair is represented as a node.
- nodes arrive over time: one node arrival at each time step.
- arriving node has type  $H$  with probability  $\theta$  (and type  $E$  w.p.  $1 - \theta$ ).

# modeling assumptions

- an incompatible patient-donor pair is represented as a node.
- nodes arrive over time: one node arrival at each time step.
- arriving node has type  $H$  with probability  $\theta$  (and type  $E$  w.p.  $1 - \theta$ ).
- compatibility between nodes is modeled as a random graph, where the probability of an arc depends on the type of the receiving node:
  - $\mathbb{P}_{H \rightarrow H} = \mathbb{P}_{E \rightarrow H} = p_H = o(1)$ .
  - $\mathbb{P}_{H \rightarrow E} = \mathbb{P}_{E \rightarrow E} = p_E = \Theta(1)$ .

# modeling assumptions

- an incompatible patient-donor pair is represented as a node.
- nodes arrive over time: one node arrival at each time step.
- arriving node has type  $H$  with probability  $\theta$  (and type  $E$  w.p.  $1 - \theta$ ).
- compatibility between nodes is modeled as a random graph, where the probability of an arc depends on the type of the receiving node:
  - $\mathbb{P}_{H \rightarrow H} = \mathbb{P}_{E \rightarrow H} = p_H = o(1)$ .
  - $\mathbb{P}_{H \rightarrow E} = \mathbb{P}_{E \rightarrow E} = p_E = \Theta(1)$ .

- no endogenous departures.

# matching technology options

- in real kidney exchanges, matches are conducted over time:
  - bilaterally,
  - in multi-way cycles,
  - through chains.

- in our model, we only consider:
  - bilateral matchings
  - chain matchings

# our measure of efficiency

## average waiting times

- infinite horizon, dynamic system, steady-state behavior.
- everyone eventually gets matched
- the E nodes typically wait very little
- $\Rightarrow$  **objective** : minimize  $w_H$ , the average waiting time for  $H$  nodes in steady-state.

# our measure of efficiency

## average waiting times

- infinite horizon, dynamic system, steady-state behavior.
- everyone eventually gets matched
- the E nodes typically wait very little
- $\Rightarrow$  **objective** : minimize  $w_H$ , the average waiting time for  $H$  nodes in steady-state.

**note:** by Little's law, if  $n_H$  is the average number of  $H$  nodes waiting in steady state, then:  $n_H = \theta w_H$ .

## lower bound on best-possible algorithms

### Proposition 1 (ABJM16)

- *under any matching policy that reaches a steady state, average waiting times are such that  $w_H + w_E = \Omega(\frac{1}{\rho_H})$ .*

**intuition:** by contradiction: if the pool size is too small, an arriving node has a small probability of being matched immediately, and must wait a “long” time to get at least an incoming arc; by Little’s law, this in turn would imply a “large” pool size.

## lower bound on best-possible algorithms

### Proposition 1 (ABJM16)

- *under any matching policy that reaches a steady state, average waiting times are such that  $w_H + w_E = \Omega(\frac{1}{\rho_H})$ .*

**intuition:** by contradiction: if the pool size is too small, an arriving node has a small probability of being matched immediately, and must wait a “long” time to get at least an incoming arc; by Little’s law, this in turn would imply a “large” pool size.

### Proposition 2 (ABJM16)

- *under any bilateral matching policy that reaches a steady state, the average waiting time of node  $H$  is such that  $w_H = \Omega(\frac{1}{\rho_H^2})$*

**intuition:** main idea is to show that a significant fraction of  $H$  nodes have to match to each other as a necessary condition for steady-state.

# bilateral matching

## *BilateralMatch-H* algorithm:

- only 2-cycles are considered.
- matches are conducted as soon as possible (myopic policy).
- in case of ties, priority is given to  $H$  agents.

## properties:

- arcs present at  $t$  are never used for a matching at a time  $> t$ .
- system is characterized by only  $N_t = (N_H(t), N_E(t))$ .
- $N_t$  is a positive recurrent Markov Chain.

## BilateralMatch-H performance

### Theorem 1 (ANJM16)

- if  $\theta < 1/2$ , BilateralMatch-H achieves a waiting time  $w_H = \Theta\left(\frac{1}{\rho_H}\right)$
- if  $\theta \geq 1/2$ , BilateralMatch-H leads to much larger waiting time  $w_H = \Theta\left(\frac{1}{\rho_H^2}\right)$

## BilateralMatch-H performance

### Theorem 1 (ANJM16)

- if  $\theta < 1/2$ , BilateralMatch-H achieves a waiting time  $w_H = \Theta\left(\frac{1}{p_H}\right)$
- if  $\theta \geq 1/2$ , BilateralMatch-H leads to much larger waiting time  $w_H = \Theta\left(\frac{1}{p_H^2}\right)$

## intuition of the proof

case  $\theta < 1/2$ : more  $E$  than  $H$  nodes:

- when there are a lot of  $E$  nodes,  $H$  nodes can easily match to them bilaterally; the probability of that happening is  $p_H$  for each  $H$  node waiting in the system.
- $\Rightarrow$  there needs to be only  $1/p_H$  nodes waiting for one to be matched with high probability at every time step ...

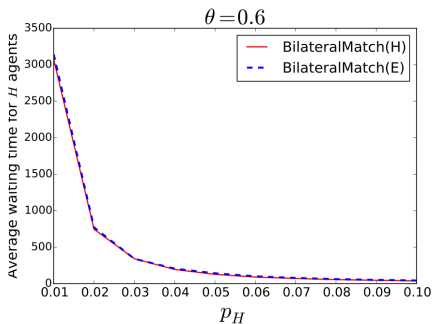

case  $\theta > 1/2$ : more  $H$  than  $E$  nodes:

- when there are few  $E$  nodes however, some  $H$  nodes have to match to each other; the probability of this happening drops to  $p_H^2$
- $\Rightarrow$  there needs to be  $1/p_H^2$  nodes waiting for one to be matched with high probability at every time step ...

## priorities - what about *BilateralMatch-E* performance?

Theorem 1 also holds for a policy that prioritizes for  $E$  nodes instead of  $H$  nodes (proved when  $p_E = 1$ , conjectured when  $p_E < 1$ )

# chain matching

## motivations

- “non-directed” donors allow for chain matching.
- very good performance in static systems.
- very widely used in kidney exchange platforms.

## known results

- chains can be used in dynamic matching [Anderson et al.].
- often at high computation cost (longest chains in the graph).

## our results

- extension to heterogeneous systems.
- good performance with myopic (greedy in time and in chain exploration) policy.
- heterogeneity helps.

# chain matching

## *ChainMatch* algorithm:

- arrival of an altruistic agent.

# chain matching

## *ChainMatch* algorithm:

- arrival of an altruistic agent.
- priority for  $H$  agents in case of a tie.

# chain matching

## *ChainMatch* algorithm:

- arrival of an altruistic agent.
- priority for  $H$  agents in case of a tie.
- we match agents as soon as possible.

# chain matching

## *ChainMatch* algorithm:

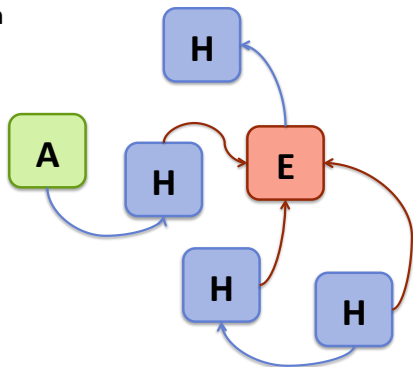

- arrival of an altruistic agent.
- priority for  $H$  agents in case of a tie.
- we match agents as soon as possible.
- the next agent is chosen randomly

# chain matching

## *ChainMatch* algorithm:

# chain matching

## *ChainMatch* algorithm:

- arrival of an altruistic agent.
- priority for  $H$  agents in case of a tie.
- we match agents as soon as possible.
- the next agent is chosen randomly

## properties:

- system is defined by  $(N_H(t), N_E(t))$ .
- Markov property.

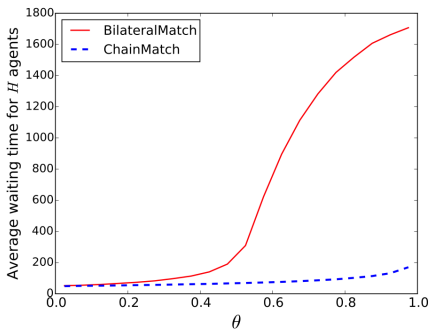

## ChainMatch performance

### Theorem 2 (ANJM16)

in the special case  $p_E = 1$ ,

- if  $\theta < 1$ , ChainMatch achieves a waiting time  $w_H = \Theta\left(\frac{1}{p_H}\right)$
- if  $\theta = 1$ , ChainMatch achieves a waiting time  $w_H = O\left(\frac{\ln(1/p_H)}{p_H}\right)$

## summary results: chain vs bilateral

## Parameters of the simulation

- ▶ 100,000 iterations
- ▶  $p_H = 0.02$
- ▶  $p_E = 0.8$

## discussion

### performance of myopic algorithms

- batching does not help reduce waiting times.
- greedy chains perform as well as longest chains.

### value of heterogeneity.

- for  $\theta < 1$ , waiting times decrease as  $\frac{1}{1-\theta}$ .
- having at least 50% of  $E$  agents allows for near-optimal performance using bilateral matching.

# takeaways

## benefits of heterogeneity

- tradeoff between complexity of the matching mechanism and performance.
- simpler chain-matching algorithm while keeping optimal performances.

Thank You !
